Differential Inhibitory Action of Nitric Oxide and Peroxynitrite on Mitochondrial Electron Transport

Adriana Cassina and Rafael Radi

Department of Biochemistry, Facultad de Medicina, Universidad de la República, 11800 Montevideo, Uruguay

Received October 12, 1995, and in revised form January 8, 1996

Various authors have suggested that nitric oxide (·NO) exerts cytotoxic effects through the inhibition of cellular respiration. Indeed, in intact cells ·NO inhibits glutamate–malate (complex I) as well as succinate (complex II)-supported mitochondrial electron transport, without affecting TMPD/ascorbate (complex IV)-dependent respiration. However, experiments in our lab using isolated rat heart mitochondria indicated that authentic ·NO inhibited electron transport mostly by reversible binding to the terminal oxidase, cytochrome a3, having a less significant effect on complex II- and no effect on complex I-electron transport components. The inhibitory action of ·NO was more profound at lower oxygen tensions and resulted in a differential spectra similar to that observed in dithionite-treated mitochondria. On the other hand, continuous fluxes of ·NO plus superoxide (O·-), which lead to formation of micromolar steady-state levels of peroxynitrite anion (ONOO-), caused a strong inhibition of complex I- and complex II-dependent mitochondrial oxygen consumption and significantly inhibited the activities of succinate dehydrogenase and ATPase, without affecting complex IV-dependent respiration and cytochrome c oxidase activity. In conclusion, even though nitric oxide can directly cause a transient inhibition of electron transport, the inhibition pattern of mitochondrial respiration observed in the presence of peroxynitrite is the one that closely resembles that found secondary to ·NO interactions with intact cells and strongly points to peroxynitrite as the ultimate reactive intermediate accounting for nitric oxide-dependent inactivation of electron transport components and ATPase in living cells and tissues.

Key Words: nitric oxide; superoxide; peroxynitrite; free radicals; mitochondria; cytochrome oxidase; nitrosothiols.

Nitric oxide (·NO, nitrogen monoxide), 2 an endogenously synthesized radical intermediate, plays an important physiologic role in different organ systems (1–3). In spite of the physiologic role of ·NO, it has become evident that it can mediate cytotoxic actions either during the normal defensive function of neutrophils and macrophages toward target cells (4–6) or by excess production in tissues undergoing diverse pathological situations (7–9).

One important mechanism by which nitric oxide exerts cytotoxicity is the inhibition of cellular respiration secondary to the inactivation of mitochondrial aconitase and components of the electron transport chain (10–12). In particular, in intact cells ·NO mediates inhibition of glutamate–malate (complex I) and succinate (complex II)-supported mitochondrial electron transport, without affecting TMPD/ascorbate (complex IV)-dependent respiration (11, 12).

Mammalian mitochondria is known to be a target for the toxic action of strong oxidants such as hydroxyl radical (13). However, ·NO itself is a weak oxidant and it interacts with a limited number of biomolecules, in particular those containing heme moieties (14, 15). Nevertheless, ·NO produced in aerobic environments can turn to a potent oxidant, by its reaction with superoxide (O·-), which yields peroxynitrite anion (ONOO-) (16–19).

Peroxynitrite 3 is a biologically generated reactive and toxic species produced under oxidative stress conditions (20–22). In vitro experiments have shown that biologically relevant concentrations of authentic peroxynitrite is used to indicate either peroxynitrite anion (ONOO-) or peroxynitrous acid (ONOOH) throughout the manuscript. The IUPAC recommended nomenclature for peroxynitrite is oxoperoxonitrate (1), for peroxynitrous acid it is hydrogen oxoperoxonitrate and for nitric oxide it is nitrogen monoxide.

2 Abbreviations used: ·NO, nitric oxide; O·-, superoxide; ONOO-, peroxynitrite anion; TMPD, N,N,N,N-tetramethyl-p-phenylenediamine; Mops, 3-(morpholino)propanesulfonic acid; SNAP, S-nitroso-N-acetylpenicillamine; BSA, bovine serum albumin; RCR, respiratory control ratio; GSNO, S-nitrosoglutathione.

3 The term peroxynitrite is used to indicate either peroxynitrite anion (ONOO-) or peroxynitrous acid (ONOOH) throughout the manuscript. The IUPAC recommended nomenclature for peroxynitrite is oxoperoxonitrate (1), for peroxynitrous acid it is hydrogen oxoperoxonitrate and for nitric oxide it is nitrogen monoxide.

oxyhnitrite inactivate mammalian heart mitochondrial electron transport components and ATPase (23), with an inactivation profile remarkably similar to the one observed during NO exposure to intact cells (24). In addition, Hausladen and Fridovich (25) and Castro et al. (26) have recently shown that mitochondrial aconitase is readily inactivated by peroxynitrite but not significantly by NO.

These considerations bring forth the possibility that the toxic effects of nitric oxide toward mitochondria observed in vivo may ultimately rely on the formation of secondary, more potent, nitrogen-derived oxidants such as peroxynitrite.

In this work we have studied the direct interactions of NO and NO plus O2 on intact rat heart mitochondria as evaluated by substrate-supported oxygen consumption, enzyme activities of individual electron transport components and ATPase, and visible absorption spectrum of cytochromes, with the aim of better defining the molecular mechanisms by which NO mediates inhibition of cell respiration.

MATERIALS AND METHODS

Chemicals. Fatty acid free bovine serum albumin (fraction V), horse heart cytochrome c (type III), rabbit muscle pyruvate kinase (type I), rabbit muscle lactate dehydrogenase (type I), glutamic acid, malic acid, succinic acid, rotenone, antimycin A, ascorbic acid, potassium cyanide, N,N,N-trimethyl-p-phenylenediamine (TMPD), NADH, 2,6-dichlorophenolindophenol, 3-(morpholinol)propanesulfonic acid (Mops), 4-(2-hydroxyethyl)-1-piperazinethanesulfonic acid (Hepes), ethylene glycol bis-(B-aminoethyl ether) N,N-tetraacetic acid (EGTA), bovine erythrocyte hemoglobin, hypoxanthine, glutathione (reduced form), and alfopurinol were obtained from Sigma (St. Louis, MO).

Xanthine oxidase from bovine milk was from Calbiochem. Bovine CuZn-superoxide dismutase was a kind gift of Grunenthal (Germany). S-nitroso-N-acetylpenicillamine (SNAP) was from BIOMOL Research Laboratories Inc. (Plymouth Meeting, PA), and Sephadex G-25 was from Pharmacia Biotech Inc. (Sweden). High purity argon and nitric oxide gas were obtained from AGA Gas Co. (Montevideo, Uruguay).

Mitochondrial preparation. Adult rats (150-220 g) were anesthetized and hearts removed and washed extensively with cold homogenization buffer until they were free of blood, minced in small fragments, and homogenized by passing the tissue through a small tissue grinder. Tissue fragments were completely disrupted using a Potter-Elvehjem homogenizer in a homogenization buffer containing 0.3 M sucrose, 5 mM Mops, 5 mM potassium phosphate, 1 mM EGTA, 0.1% BSA. The homogenate was centrifuged at 1500g to eliminate large pieces of tissue and mitochondria were isolated from the supernatant by centrifugation at 10,000g. Mitochondrial pellets were resuspended in a minimal volume of homogenization buffer to 25-35 mg protein/ml and kept under ice at 4°C until used. Respiratory control ratio (RCR) for complex II-dependent respiration, typically ranged between 3 and 5.

Preparation of nitric oxide, SNAP, and S-nitrosothiol. A stock nitric oxide solution was obtained by flushing nitric oxide gas for 10 min in a gas-sampling tube containing high purity deoxygenated water, which had been previously deoxygenated by extensive bubbling with argon for 30 min. The nitric oxide concentration achieved in solution was 1.5 mM at 25°C, which is close to saturation levels. Nitric oxide concentration was determined by measuring the oxidation of oxyhemoglobin to methemoglobin according to (27) or by electron-chemical detection using a nitric oxide sensor (ISO-NO, World Precision Instruments, Inc., Sarasota, FL).

S-nitrosothiol (GSNO) was synthesized at 25°C by reacting equimolar (200 mM) concentrations of reduced glutathione with sodium nitrite in 100 mM HCl, obtaining a reaction yield greater than 95% (28). Solutions of SNAP were prepared in 25 mM H2SO4 (29). Peroxynitrite was synthesized from sodium nitrite and hydrogen peroxide using a quenched-flow reactor, as previously (17, 18). Excess hydrogen peroxide was eliminated with manganese dioxide. Peroxynitrite concentration was assayed spectrophotometrically at 302 nm (ε = 1.67 mM-1 cm-1).

Oxygen consumption studies. Mitochondrial respiration was measured polarographically using a Cole-Palmer oximeter fitted with a water-jacketed Clark-type electrode (YSI Model 5300) in a 1.0-ml reaction vessel. Oxygen consumption studies were performed in homogenization buffer at 37°C, pH 7.4, at 0.2-0.5 mg/ml mitochondria. Glutamate malate (2.5 mM), succinate (5 mM), or ascorbate (5 mM) plus TMPD (0.5 mM) were used to quantitate complex I, II, and IV-dependent respiration, respectively.

Mitochondrial exposure to reactive species. For mitochondrial exposure to nitric oxide, intact mitochondria (1 mg/ml) and frozen-thawed mitochondria were incubated under anaerobic conditions in rubber-capped tubes in 100 mM phosphate buffer, pH 7.4, and were exposed to either authentic nitric oxide (5-200 µM) or S-nitrosothiols (GSNO, SNAP). Aliquots of the mitochondrial suspensions were taken through the rubber septum with gas-tight Hamilton syringes and mitochondrial-dependent oxygen consumption and enzymatic activities were measured. Also, exposure to nitrate and nitrite (5-200 µM) were performed.

Mitochondrial suspensions (2 mg/ml) were also exposed to aerobic incubations with 150 µM hypoxanthine plus 5.5 munits/ml xanthine oxidase which generate O2 and hydrogen peroxide (H2O2) for 30 min in 100 mM phosphate buffer, pH 7.4. The rates of formation of uric acid (ε290 = 11 mM-1 cm-1) and O2, followed as the superoxide dismutase-inhibitable reduction of cytochrome c (ε550 = 21 mM-1 cm-1), were measured spectrophotometrically. The univalent flow percentage was 19%, representing a superoxide flux of 4.2 µM/min. Xanthine oxidase-dependent reactions were stopped by addition of 100 µM allopurinol and mitochondrial suspensions washed once at 12,000g for 10 min, before running oxygen consumption studies.

A NO flux was introduced in the reaction mixtures by the decomposition of GSNO (5 mM) as determined by oxidation of oxy- to metheoglobin at 577 nm (ε = 11 mM-1 cm-1; Ref. 27).

Enzyme assays. Succinate dehydrogenase was measured spectrophotometrically in the presence of 20 µM DCPIP, 15 mM succinate, and 2 µM KCN. Reduction of DCPIP was followed at 600 nm (ε = 20.5 mM-1 cm-1) (30). NADH dehydrogenase activity was quantitated by the rate of NADH-dependent ferricyanide reduction at 420 nm (ε = 1 mM-1 cm-1) (31), using 200 µM NADH and 0.5 mM ferricyanide in the presence of 5 µM rotenone. Cytochrome c oxidase activity was determined at the rate oxidation of 30 µM reduced cytochrome c at 550 nm (ε = 20.5 mM-1 cm-1) (31). Reduced cytochrome c was prepared by reduction of cytochrome c with excess sodium dithionite, followed by Sephadex-G25 chromatography. ATPase activity was assayed by coupling the reaction of pyruvate kinase with lactate dehydrogenase and following NADH oxidation at 340 nm (ε = 6.22 mM-1 cm-1) (32). The assay system for ATPase activity contained 2.5 mM ATP, 50 µM pyruvate, 50 µM lactate dehydrogenase in 50 mM Hepes, pH 8.

Nitric oxide determinations were performed either in a Kontron Analytical Model SFM 25 or a Shimadzu UV 160 spectrophotometers, using 0.1-0.2 mg/ml mitochondrial protein. Protein concentrations were determined using the method of Bradford (33).

Visible absorption differential spectra of mitochondrial cytochromes. The differential spectrum of mitochondria (1 mg/ml) under different experimental conditions was determined in the 500 to 630 nm region in 0.3 M sucrose, 5 mM Mops, 5 mM potassium phosphate, 1 mM EGTA, pH 7.4, using a Spectronic 3000 Array spectrophotometer in...
RESULTS

Inhibition of Mitochondrial Respiration by Nitric Oxide and Peroxynitrite

Sequential bolus additions of authentic NO (5–15 μM) to mitochondrial suspensions in respiration buffer and at oxygen tensions ranging from 220 μM (air-saturated buffer) down to 65 μM, resulted in inhibition of complex I- and II-dependent, state-4 and state-3 (ADP-estimated) respiration, an effect that was more evident at lower oxygen concentrations in the respiration buffer (Figs. 1A–1G). Indeed, at 65 μM oxygen, 5 μM NO caused near 100% inhibition of the rate of complex I and II-oxygen uptake in state-4 and -3 (Figs. 1B, 1C, and 1E–1G, respectively).

Interestingly, the inhibitory action of NO was overcome by gentle bubbling of mitochondrial suspension with air for 10 s, resulting on 100% recovery of complex I- and IV-dependent oxygen consumption (Figs. 1B, 1C, and 2) and near 50% of complex II-dependent respiration (Figs. 1E–1G). Even when mitochondria were preincubated at high NO concentrations (200 μM) and then diluted 5-fold for oxygen consumption studies (final NO concentration 40 μM) reoxygenation resulted in 100% recovery of TMPD/ascorbate-dependent respiration (Fig. 2).

The transient inhibition by NO did not result in mitochondrial uncoupling. For instance, after NO displacement from mitochondrial suspensions following reoxygenation, addition of ADP (180 μM), to succinate-supported respiration resulted on state-3 respiration oxygen consumption rates similar to control mitochondria (Fig. 1E).

On the other hand, a flux of peroxynitrite inhibited complex I- and II-dependent respiration by 20 and 80%, respectively, without affecting complex IV-dependent respiration (Table I). The inhibitory effects of peroxynitrite on mitochondrial respiration were maintained after mitochondrial washings. This is different to what is observed with NO, since after mitochondrial washings only a marginal inhibition of complex I- and IV-dependent respiration remained, with a partial (40%) inhibition at complex II, which still was significantly less than that caused by a equimolar flux of peroxynitrite (80%) (Table I). Neither nitrite nor nitrate (up to 200 μM), the end products of NO and peroxynitrite decomposition had any significant effect on mitochondrial respiration (data not shown).

Spectral Changes Induced by Nitric Oxide and Peroxynitrite

The visible differential spectrum (reduced minus oxidized) of dithionite-treated rat heart mitochondrial preparation showed the typical absorption bands in the 500 to 650 nm region, corresponding to the reduced forms of the mitochondrial cytochromes (c, b, and aa₃) in the presence of sodium dithionite (Fig. 3A). Similarly, anaerobic incubation of mitochondria with NO (50 μM) resulted in the appearance of bands corresponding to cytochrome aa₃ and c (Fig. 3B). Further addition of succinate to the NO-treated mitochondria also made the cytochrome b band evident (Fig. 3C). When mitochondria were exposed to succinate plus antimycin A, only the band of cytochrome b was evident (Fig. 3D), but interestingly, further addition of NO (under anaerobic conditions) resulted in the appearance of an additional band corresponding to cytochrome aa₃ (Fig. 3E). The mitochondrial differential spectrum was not modified by either aerobic or anaerobic exposure to up to 1 mM authentic peroxynitrite (data not shown).

Inactivation of Mitochondrial Enzymes by Nitric Oxide Plus Superoxide

A peroxynitrite flux was obtained from the generation of equimolar fluxes of 4.2 μM/min NO from nitrosoglutathione and O₂⁻ from xanthine oxidase and resulted in the formation of peroxynitrite, as quantitated by the rate of oxidation of cytochrome c² to cytochrome c³, as reported recently (34). Under our assay conditions cytochrome c³ (30 μM) oxidation yields using authentic peroxynitrite (10 μM) were 50%. Thus, a rate of cytochrome c³ oxidation of 2.0 μM/min corresponded to a peroxynitrite flux of 4.0 μM/min (Fig. 4). Peroxynitrite formation was stopped by addition of the xanthine oxidase inhibitor, allopurinol. Indeed, allopurinol addition to the reaction mixture inhibited the oxidation of cytochrome c³ by 90%.

Then, exposure of mitochondrial suspensions to a flux of 4.0 μM/min peroxynitrite for 20 min resulted on a decrease of succinate dehydrogenase and ATPase activities by 50 and 86%, respectively, without inhibition of NADH dehydrogenase (Table II). However, exposure to independent fluxes of either nitrosoglutathione- or xanthine oxidase-derived NO or xanthine oxidase-derived O₂⁻ did not result in lower enzyme activities of NADH dehydrogenase, succinate dehydrogenase, and ATPase than in the control samples (Table II). Moreover, aerobic or anaerobic addition of authentic NO (60 μM) to mitochondrial suspensions did not result in inactivation of these enzymes after 20-min incubations. On the other hand, cytochrome c oxidase activity was inhibited after 20-min incubation with GSNO (5 mM aerobically) and authentic NO (10 μM anaerobically) by 70 and 40%, respectively. The inhibitory effect of NO on cytochrome c oxidase activity was significantly overcome in the presence of xanthine oxidase (Table II).

Neither nitrite nor nitrate (up to 200 μM) had inhibitory effects on the studied enzyme activities (not...
FIG. 1. Effect of \(^{15} \text{NO}\) on substrate-dependent mitochondrial oxygen consumption. State-4 and state-3 oxygen consumption in presence of respiratory substrate and different concentrations of \(^{15} \text{NO}\) was studied in mitochondria, at 220 \(\mu\text{M}\) (A,D) and 65 \(\mu\text{M}\) (B,C,E,F,G) initial oxygen concentration, using a polarographic Clark-type electrode at 37°C. The reaction vessel contained 1.0 ml final reaction volume. Concentration of added compounds are indicated in the figure. Numbers are rates of oxygen consumption in nmol min\(^{-1}\). Note: Reoxygenation (REOXYGEN.) of the reaction mixture was accomplished by gentle bubbling for 10 s with air. Afterward, rate recording was restarted once oxygen concentration approached the same value existing right before reoxygenation.

shown) which correlates with the lack of effect on oxygen consumption.

DISCUSSION

In this work we have demonstrated a differential action of \(^{15} \text{NO}\) and peroxynitrite on the activity of electron transport chain components and rates of oxygen consumption on isolated mammalian mitochondria. Inhibition of mitochondrial respiration by \(^{15} \text{NO}\) was reversible and the effect was more pronounced at lower oxygen tensions (Fig. 1). Nitric oxide interaction with mitochondria caused inhibition of complex I-, II-, and
IV-dependent respiration (Figs. 1 and 2). The inhibition could be overcome by removing ·NO from the mitochondrial suspensions through bubbling with air which returned oxygen consumption rates of state-4 and state-3 respiration to values similar to initial ones. The reversibility of ·NO inhibition was further evidenced by preincubation with high ·NO concentrations (200 μM), since dilution and reoxygenation of mitochondrial suspensions resulted in near 100% recovery of TMPD/ascorbate (complex IV)-dependent oxygen consumption rates. In addition, the data indicate that ·NO did not cause significant uncoupling of mitochondria.

Considering the high affinity of ·NO for hemeproteins, its ability to inhibit complex IV-dependent respiration (Fig. 2) and cytochrome c oxidase activity (Table I), and the competition observed with molecular oxy-
we conclude that ·NO binding to the heme moiety of cytochrome a₃ is one key mechanism accounting for ·NO-mediated inhibition of mitochondrial respiration. This idea is in line with recent publications that show similar effects of nitrosothiols on brain mitochondria.

To further support this concept, our data show that ·NO plus succinate resulted in a differential spectra similar to that observed in dithionite-treated mitochondria, in which cytochrome aa₃, b, and c were evidenced (Fig. 3). This was presumably due to the combination of two events, that is ·NO binding to cytochrome a₃ and reduction of electron transport chain components by endogenous (Fig. 3B) or exogenously added substrate (Fig. 3C). Moreover, in addition to binding to a reduced form of cytochrome a₃, ·NO may perform a one-electron donation to ferric cytochrome a₃ to form a nitrosyl complex in which ·NO has a character of nitronium ion (NO⁺) (37). Indeed, in succinate plus antimycin A-treated mitochondria, where only the cytochrome b is observed (Fig. 3D) and electron flow inhibited (38), addition of ·NO resulted in the appearance (35) or authentic ·NO in synaptosomal respiration (36).

Note. Freshly isolated mitochondria (1 mg/ml) was incubated with xanthine oxidase (5 μU/ml) plus hypoxanthine (150 μM), GSNO (5 mM, rate of NO release = 5 μM/min) and xanthine oxidase plus hypoxanthine in the presence of GSNO in 100 mM potassium phosphate pH 7.4 for 30 min at 25°C. The reactions were inhibited by allopurinol (100 μM) and suspensions were washed once before running oxygen consumption studies in the presence of either, glutamate/malate, succinate, or TMPD/ascorbate. Control rates were 21, 103, and 115 nmol/min/mg for complex I, II, and IV, respectively. Data represent X ± SD, n = 3.

² Data in parenthesis refer to studies performed prior to washing (thus GSNO present).
of the cytochrome aa₃ band (Fig. 3E), suggesting that·NO can directly reduce cytochrome a₃ under anaerobic conditions. Since·NO did not inactivate components of the electron transport chain (Table II), we conclude that the effect of·NO on mitochondrial respiration was mostly due to binding and inhibition at the cytochrome a₃ level, although some extent of permanent inhibition appears to be present in complex II also (Figs. 1E–1G and Table I).

On the other hand, it was previously shown that authentic peroxynitrite causes inhibition at complex I- and II- but not complex IV-dependent respiration and inactivates electron transport chain components, preferentially succinate dehydrogenase, and ATPase (23). In this work, mitochondria exposed to fluxes of O₂⁻ and·NO, which lead to peroxynitrite formation, had a pattern of inhibition of oxygen consumption (Table I) and enzyme inactivation (Table II) identical to the one previously obtained with pure peroxynitrite (23). This pattern shows a higher sensitivity of complex II in comparison to complex I to peroxynitrite (Table I). It was important to compare the outcome of mitochondrial electron transport exposed to a flux of O₂⁻ and·NO in comparison to pure peroxynitrite as we have recently observed that sometimes·NO may down-regulate O₂⁻ and peroxynitrite-dependent oxidative damage by participating in termination reactions with secondary radical intermediates (39). Thus, a rather striking conclusion is that inhibition of isolated mitochondrial respiration induced by peroxynitrite (and not by·NO) is the one that closely resembles the inhibition pattern observed during·NO exposure to intact cells (24). The differential inhibitory action of·NO and peroxynitrite on the electron transport chain relies on molecular mechanisms comparable to those observed during their interaction with mitochondrial aconitase, in which·NO forms a transient inhibitory complex with an iron center of a protein (i.e., cytochrome a₃), while peroxynitrite causes oxidation and disruption of active sites (26).

Mitochondria is a key cellular source of O₂⁻ and we have shown before that peroxynitrite-mediated oxidative damage to mammalian mitochondria results in increased substrate-supported O₂⁻ formation (23). Nitric oxide reaction with mitochondrial-derived O₂⁻ would result in “site specific” formation and reactivity of peroxynitrite at the O₂⁻ generating sites, complexes I and II (38, 40). Thus, we postulate that·NO can initially bind to cytochrome a₃ producing a transient inhibition of normal electron flow (and ATP synthesis, Ref. 41) and promoting electron leakage to oxygen yielding O₂⁻. Superoxide could then react with other·NO molecules diffusing to mitochondria to form peroxynitrite which would, in turn, cause inhibition of electron flow.

Note. Mitochondria (1 mg/ml) was incubated with anaerobic NO (10 µM), GSNO (5 mM, rate of·NO release = 5 µM/min), and xanthine oxidase (5 mU/ml) plus hypoxanthine (150 µM) in 100 mM potassium phosphate, pH 7.4, for 30 min at 25ºC. The reaction was inhibited by allopurinol (100 µM) and NADH dehydrogenase, succinate dehydrogenase, ATPase, and cytochrome c oxidase activity assayed spectrophotometrically. 100% activity corresponded to 400, 47, 99, and 41 µM/min/mg for NADH dehydrogenase, succinate dehydrogenase, ATPase, and cytochrome c oxidase, respectively. Data represent X ± SD, n = 3.
and enhanced $O_2^-$ formation, continuing a self-propagated peroxynitrite-dependent injury process. In conclusion, our data support the concept that peroxynitrite, and not $^1$NO, is responsible for the electron transport inhibition observed during $^1$NO challenge to target cells and tissues.
